FOREWORD

The work described in this report was carried out for the National Aeronautics and Space Administration, Ames Research Center, Moffett Field, California, 94035, under the terms and specifications of their Contract NAS 2-3496.

The work was performed in the Aerospace Sciences Laboratory, R. Capiaux, Manager, of the Lockheed Palo Alto Research Laboratory.

ABSTRACT

The spectral absorption coefficients of neutral and singly ionized carbon nitrogen, and oxygen atoms are presented. The continuum contributions resulting from bound-free and free-free transitions are presented in terms of an effective cross section summed over all permissible initial and final states. These effective continuum cross sections are tabulated spectrally over a frequency range $0.25 \text{ eV} \leq h\nu \leq 20 \text{ eV}$ for temperatures in the range $3,000^{\circ}\text{K}$ to $24,000^{\circ}\text{K}$ at $1,000^{\circ}\text{K}$ intervals. The discrete, i.e. line, contributions resulting from bound-bound transitions are presented in terms of tabulations of absorption f-numbers for all significant transitions (multiplet, supermultiplet, and transition arrays). Electron impact (half) half-widths and line shifts for Lorentzian line shapes are tabulated for all significant transitions for temperatures in the range $2,500^{\circ}\text{K}$ to $25,000^{\circ}\text{K}$.

ACKNOWLEDGMENTS

The authors acknowledge with gratitude the many helpful discussions and efforts of Dr. R. Johnston, Dr. P. Kelley, and O. Platas of the Physical Sciences Laboratory, Lockheed Palo Alto Research Laboratory. Particular thanks are extended to Antoinette Dandridge for her competence and conscientious work on the many computer calculations required.

NOMENCLATURE

$b_{nn'}$	normalized line shape function
CI	spectroscopic notation for neutral carbon atoms
CII	spectroscopic notation for singly ionized carbon atoms
$C_{11'}$	algebraic factor obtained from integration over spin and angular coordinates
c	velocity of light in vacuo, 3.00×10^{10} cm/sec
$d_{nn'}$	electron impact line shift
e	electronic charge, 4.80×10^{-10} esu
$f_{nn'}$	absorption f-number
$f(v)$	Maxwellian velocity distribution
G_{11}^z	numerical quantity tabulated in Ref. 9
\bar{q}	average Gaunt factor
h	Planck constant, 4.135×10^{-15} eV sec
$h\nu$	frequency variable in eV units
K^z	Kramer's semiclassical cross section
k	Boltzmann constant, 8.617×10^{-5} eV/ $^{\circ}$ K
L'	total angular momentum of the electron-atom system in the final state
l, l'	orbital angular momentum of initial and final states for bound-free transitions
$l_n, l_{n'}$	orbital quantum numbers for electron in states n, n'
m	electron mass, 9.11×10^{-28} gm
N	particle number density
NI	spectroscopic notation for neutral nitrogen atoms
NII	spectroscopic notation for singly ionized nitrogen atoms
\bar{n}	effective quantum number
OI	spectroscopic notation for neutral oxygen atoms
OII	spectroscopic notation for singly ionized oxygen atoms
$P_n, P_{n'}$	radial wave functions for atomic system in states n, n'

Q	partition function
Ry	Rydberg constant, 13.60 eV
r	radial coordinate in dipole integral evaluation
T	temperature
u_0	nondimensional ionization energy
u	nondimensional frequency, $h\nu/kT$
u_g	nondimensional threshold frequency for integration over excited states
v	electron velocity
Z	charge on residual ion
Γ	ratio of partition functions in Biberman's theory
$\gamma_{nn'}$	electron impact line width
γ	parameter taken from Ref. 10
μ	absorption coefficient
μ_n'	effective quantum number, Eq. (3.6)
σ	cross section
σ_0	dimensional constant, Eq. (2.3)
ν	frequency variable
ϵ	normalized energy of free electrons
ϕ	numerical quantity tabulated in Ref. 9
χ	ionization energy from ground state
$\delta_{l'}$	phase shift
ω	wave number
ξ	nonhydrogenic function in Biberman's theory
ζ	normalization factor for bound state

Subscripts:

k	denotes species
i, j	initial, final states for bound-free transition
i', j'	initial, final states for free-free transition
n, n'	initial, final states for bound-bound transition
e	denotes free electrons

Superscripts:

- k denotes species
- b-f bound-free transition
- f-f free-free transition
- b-b bound-bound transition
- C continuum contribution
- T threshold value

Section 1

INTRODUCTION

The ability to predict radiant energy transfer is essential in the study of shock-heated plasma flows. In the case of bodies entering planetary atmospheres at high velocities (roughly greater than 10 km/sec), radiation transport is significant in determining the shock-layer structure and surface energy transfer. A knowledge of the frequency-dependent absorption properties of the constituent species is required in these quantitative studies of radiation transport.

Theoretical methods for calculating the spectral absorption coefficients of atomic plasmas of light elements are now well developed (Ref. 1). These methods have been applied previously to opacity calculations for nitrogen and oxygen atoms (Ref. 2) and recently to carbon atoms. The results of this work are summarized in this report in terms of detailed tabulations of spectral absorption coefficient data for neutral and singly ionized carbon, nitrogen, and oxygen atoms.* These atoms, along with hydrogen, for which the requisite spectral data are available (Refs. 1 and 4), are likely to be the dominant atomic species in planetary entry problems or problems involving surface mass injection from hydrocarbon-based ablation heat shields. Hence, this report provides a necessary counterpart to existing tabulations of molecular opacities of H, C, N, and O mixtures. (See, for example, Refs. 5, 6, and 7.)

For atomic systems, photon absorption results from the interaction of free-free, bound-free, and bound-bound electron transitions with the radiation field. The first two processes give rise to a continuous variation of absorption coefficient with photon

*The standard spectroscopic notation of representing the ionized state of an atom by a Roman numeral following the atomic symbol (Ref. 3) is used in this report. Hence, the neutral nitrogen atom is written NI, the singly ionized nitrogen atom NII, etc.

frequency, while the latter process in principle occurs only at a discrete photon frequency and gives rise to line absorption. The absorption coefficient for species k can be written as (Ref. 2)

$$\mu_k(h\nu) = \sum_{i,j} N_i^k \sigma_{ij}^k (h\nu) \quad (1.1)$$

where N_i^k is the number density for lower state i of species k, and $\sigma_{ij}^k (h\nu)$ is the frequency dependent* cross section for photon absorption resulting from a transition from state i to j of species k. Following common practice, the continuum absorption coefficient is presented separate from the line absorption coefficient; in Section 2 we discuss the calculation of free-free and bound-free cross sections, and in Section 3 the calculation of bound-bound cross sections.

Both the effective bound-free cross sections introduced in Section 2 and line width calculations discussed in Section 3 rest upon the assumption of local thermodynamic equilibrium at a specified temperature. Accordingly, data are presented at selected temperatures in the range from 3000°K to 24,000°K. It is intended that the data tabulated in this report will be adequate for radiation transport problems in which the local temperature is less than 24,000°K ($kT \sim 2$ eV). Using this temperature as a guide, cross sections for photon frequencies covering a range of 0.25 to 20 eV are tabulated. The lower frequency limit is set by limitations on the bound-free continuum absorption coefficients. These limitations result from uncertainties in the populations of the very high excited states without proper accounting of plasma interactions. However, the lower limit of 0.25 eV will be adequate for the large class of radiation transport problems where little energy is transported at frequencies lower than 0.25 eV. The upper frequency limit reflects the fact that for a blackbody source at a temperature of 2 eV, over 99 percent of the total radiated power is emitted at frequencies below this upper limit.

*Throughout this report, the unit of frequency used is the energy unit $h\nu$ in electron-volts (eV). In addition, it will often be convenient to express temperature as an energy unit kT in electron-volts, k being the Boltzmann constant, 8.6170×10^{-5} eV/°K.

Tabulations of the spectral absorption properties of carbon, nitrogen, and oxygen atoms are given in Section 4. The first set of tables presents the total effective continuum cross section. The second set of tables lists the line transitions and the corresponding transition f-numbers. The final set of tables lists the line transitions and the temperature dependent electron impact half-width and line center shift for these transitions.

Section 2
CONTINUUM ABSORPTION CROSS SECTIONS

2.1 THEORETICAL METHODS

The continuum absorption coefficient is determined from the general expression

$$\mu_k^C = \sum_{i,j} N_i^k \sigma_{ij}^{b-f} (h\nu) + \sum_{i',j'} N_{i'}^k \sigma_{i',j'}^{f-f} (h\nu) \quad (2.1)$$

where $\sigma_{i,j}^{b-f} (h\nu)$ is the frequency-dependent cross section for photon absorption resulting from an electron transition from bound state i to a free state k ; and similarly, $\sigma_{i',j'}^{f-f} (h\nu)$ is the frequency-dependent cross section for photon absorption resulting from an electron transition from free state i' to free state j' .*

The bound-free and free-free transitions for each atomic state i can be summed over all accessible final states. Thus,

$$\sigma_i (h\nu) = \sum_j \sigma_{i,j} (h\nu)$$

There are far too many states i for the complex atoms of interest to tabulate detailed $\sigma_i (h\nu)$ values for each individual state. Instead, an effective total continuum cross section is tabulated for each species k as defined by

$$\sigma_k^C (h\nu) \equiv \frac{\mu_k^C (h\nu)}{N^k} = \sum_i \frac{N_i^k}{N^k} \sigma_i^{b-f} (h\nu) + \sum_{i'} \frac{N_{i'}^k}{N^k} \sigma_{i'}^{f-f} (h\nu) \quad (2.2)$$

where N^k is the total number density of species k .

*The free state of an electron considered for photon absorption is the state of a paired electron-ion system with the electron in the continuous spectrum of energy levels. Hence, the free-free absorption coefficient is calculated in terms of a specific electron-ion pair.

Only under local thermodynamic equilibrium, where the relative populations of states N_i^k/N^k are uniquely specified by the local temperature, can the summations in Eq. (2.2) be evaluated in a reasonable manner. Hence, the effective cross-section data in this report are restricted to systems in local thermodynamic equilibrium and are tabulated at selected temperatures.

Armstrong and his co-workers have developed a computer code (PIC) for calculating bound-free (photoionization) cross sections for the states of nitrogen and oxygen atoms (Ref. 2). To the authors' knowledge, this work is the first systematic calculation of bound-free cross sections using nonhydrogenic theory for the large number of states necessary to determine detailed spectral absorption coefficient data. The tabulated effective continuum cross-section data presented for nitrogen and oxygen are taken directly from these detailed photoionization calculations together with free-free cross sections calculated according to the theory outlined below. A summary of the theory underlying the PIC code (described in detail in Ref. 2) is also presented below.

Similar detailed photoionization cross-section calculations are not available for carbon atoms. Biberman (Ref. 8) has developed a method for calculating continuum cross sections of complex atoms (both bound-free and free-free) using an approximate version of the basic Burgess-Seaton theory underlying the Armstrong calculations. Biberman's method was used to calculate the continuum cross sections for carbon which are tabulated in this report. It should be noted that the approximate theory agrees well with the detailed Armstrong results. Hence Biberman's formulae provide closed-form expressions which are quite convenient in radiation transport calculations.

2.1.1 Full Numerical Calculation of Continuum Cross Sections

The cross sections for the individual states are of the form

$$\sigma_i^{b-f}(h\nu) = \sigma_i^{b-f}(h\nu) \quad \text{for} \quad h\nu \geq h\nu_i^T$$

$$\sigma_i^{b-f}(h\nu) = 0 \quad \text{for} \quad h\nu < h\nu_i^T$$

where the threshold frequency for each bound state $h\nu_i^T$ depends on the ionization energy of that state. In the frequency range of interest, the primary contributions to the effective cross section come from the near-threshold regions of the contributing states. A theory for near-threshold transitions has been developed by Burgess and Seaton (Ref. 9). They present the photoionization cross sections of the individual states in the parameterized form

$$\sigma_i^{f-b}(h\nu) = \sigma_0 \sum_{\ell'=\ell \pm 1} C_{\ell\ell'}(L') \frac{G_{\ell\ell'}^2(\nu) \cos^2 [\varphi(\ell, \ell', \nu; \epsilon) + \delta_{\ell'}(L', \epsilon)]}{[1 + \epsilon^2] [\gamma_{\ell\ell'}(\epsilon) - 1]} \quad (2.3)$$

where the dimensional constant σ_0 is given by

$$\sigma_0 = \frac{8.55 \times 10^{-19}}{\xi(\bar{n})} \left(\frac{\bar{n}}{Z+1} \right)^2 \text{ cm}^2$$

where \bar{n} is the effective quantum number defined by

$$\bar{n} = (Z+1) \left(\frac{R_\infty}{\chi_i} \right)^{1/2}$$

and where the quantities $C_{\ell\ell'}(L')$, $G_{\ell\ell'}$, ψ and γ were obtained from tables or analytic expressions given in Ref. 9. The normalization factor $\xi(\bar{n})$ and the phase shift

$\delta(L', \epsilon)$ were estimated from information on the bound states of the ion.* The quantity χ_i^Z is the ionization energy of the i^{th} state.

In principle, one can use Eq. (2.3) and tables of populations to evaluate Eq. (2.2) directly. In practice, this is quite difficult (and unnecessary) due to the very large number of states involved. The approach taken in the present calculation was to include the low-lying states separately, then to progressively lump the higher lying states into approximately equivalent states of the properly averaged (quantum mechanically) energies. Burgess-Seaton cross sections were used for the low-lying states; hydrogen-like cross sections taken from the work of Karzas and Latter (Ref. 10) were used for the high-lying states. The states included and the energies assigned to them are given in Table 2-1.

The populations of the states were taken from the work of Gilmore (Ref. 11). The population ratios (N_i^k / N^k) were taken to be density independent and assumed a maximum principal quantum number of 8. A considerably larger number of states were included in the photoionization calculation than were considered by Gilmore. Thus, Gilmore's states were split into component states (as required) according to the statistical weights of the component states. The energy of each component state was taken to be the same as that of Gilmore's original state.

The cross section of each state was evaluated at energies of 0, 1, 2, 4, 8, 10, and 20 eV above its threshold frequency. These data were then stored on tapes. At a given frequency, the cross sections of the contributing states were obtained by logarithmic interpolation between stored values. They were then weighted by the appropriate population and summed to obtain the effective cross section.

The effective cross section σ_k^{f-f} for free-free transitions of electrons in the field of positive ions of charge $Z + 1$ can be written as (Refs. 12, 13)

$$\sigma_k^{f-f} (h\nu) = \sum_{i'} \frac{N_{i'}^k}{N^k} \sigma_{i'}^{f-f} (h\nu) = \frac{N_e N_k^{Z+1}}{N_k^Z} \bar{g} K^Z \quad (2.4)$$

*The reader is referred to Ref. 2 for the details of this calculation.

where N_e and N_k^Z are the number densities of the free electrons and the Z^{th} positive ion of species k , respectively. Kramer's semiclassical absorption coefficient, K^Z , is given by

$$K^Z = \frac{4}{3\sqrt{6}\pi} \left(\frac{2\pi e^2}{hc} \right) \left(\frac{e^2}{mc^2} \right)^2 \left(\frac{mc^2}{kT} \right)^{1/2} \frac{1}{\omega^3} \quad (2.5)$$

and \bar{g} is the Gaunt factor averaged over the Boltzmann velocity distribution of the free electrons. The quantity ω is the wave number in cm^{-1} , and m is the mass of an electron; the other physical quantities are in standard notation.

The Gaunt factor has been calculated by Karzas and Latter (Ref. 10) as a function of the dimensionless parameters u and γ^2 where

$$u = h\nu/kT$$

$$\gamma^2 = (Z + 1)^2 \frac{h \text{Ry}}{kT}$$

and Ry is the Rydberg constant.

The effective cross section $\sigma_k^{f-f}(h\nu)$ defined by Eq. (2.4) is derived for an electron-ion pair N_e , N_k^{Z+1} . It is convenient to relate the number density of electron-ion pairs to the number density of the parent atom, N_k^Z . In this manner, the free-free cross sections can be assigned to the parent atom and tabulated as part of the total continuum cross section for that atom. Assuming ionization equilibrium,* the Saha equation (Ref. 4) yields

$$\frac{N_k^{Z+1} N_e}{N_k^Z} = \left(\frac{2\pi m k T}{h^2} \right)^{3/2} \frac{2 Q_k^{Z+1}(T)}{Q_k^Z(T)} e^{-\chi^Z/kT} \quad (2.6)$$

*The assumption of ionization equilibrium is more stringent, of course, than the assumption of local thermodynamic equilibrium and hence places an additional restriction on the use of the tabulated data.

where χ^Z and $Q_k^Z(T)$ are the ionization energy and partition function, respectively, of the parent atom, and $Q_k^{Z+1}(T)$ is the partition function of the ion. Substituting Eqs. (2.5) and (2.6) into Eq. (2.3) and rearranging slightly yields the desired cross section,

$$\sigma_k^{f-f}(h\nu) = 1.26 \times 10^{-19} \frac{T}{(h\nu)^3} \frac{Q^{Z+1}}{Q^Z} e^{-\chi^Z/kT} g(u, \gamma^2) \quad (2.7)$$

where the numerical coefficient has been evaluated from physical constants.

Equation (2.7) has been evaluated at each frequency and temperature and for each atom considered. The partition functions were taken from Gilmore's report (Ref. 11) and are consistent with the occupation numbers used in the PIC code calculation (maximum quantum number of 8). The ionization energies were taken from Moore's tables (Ref. 3). Each Gaunt factor was obtained from the two-dimensional array given by Karzas and Latter by linear interpolation on the logarithm of its independent variables.

2.1.2 Approximate Theory of Biberman

Biberman and Norman (Ref. 8), using the quantum defect method, have devised an approximate theory for continuum cross sections (including both bound-free and free-free transitions) of complex neutral and ionized atoms. The resulting equations have the virtue of simplicity, being as simple as the old hydrogenic expressions, but are considerably more accurate.

The energy levels of a complex atom (for both the bound and free electron states) are divided into two groups: Group A, for which the azimuthal quantum number $\ell \leq 2$; Group B, for which $\ell > 2$. The cross section for states belonging to Group B are considered hydrogenic; those belonging to Group A are calculated using an approximation to the quantum defect method. Define a quantity $\xi(h\nu, T)$ for Group A levels as

$$\mu(h\nu, T) = [\mu(h\nu, T)]_{hyd.} \xi(h\nu, T)$$

where the quantity $[\mu(h\nu, T)]_{\text{hyd.}}$ is obtained using the hydrogenic cross sections.

The function $\xi(h\nu, T)$ is the same for both bound-free and free-free transitions.

Calculated values for $\xi(h\nu, T)$ for a number of interesting light elements are presented in Ref. 8. In particular, for carbon, nitrogen, and oxygen atoms (neutral and ionized), ξ is found to be independent of temperature. For all temperatures, therefore, $\xi(h\nu)$ is given by the single frequency function plotted in Fig. 2-1. The scaled frequency variable $h\nu/Z$ (where Z is the charge on the residual ion) is used in Fig. 2-1, which allows $\xi(h\nu)$ for ionized atoms to be shown on the same scale.

In addition to accounting for the nonhydrogenic behavior of the cross sections, Biberman showed that the effects of the increased term structure (both multiplet structure and displaced terms) for a complex atom with several valence electrons can be accounted for by a factor $\Gamma = 2Q_k^{Z+1}/Q_k^Z$. Again, Q_k^{Z+1} is the partition function of the residue ion and Q_k^Z is the partition function of the parent atom.

Using the ideas briefly described above, the following expressions for the effective continuum cross section for a particular species k are derived in Ref. 8:

$$\sigma_k^C(h\nu) = \frac{6.26 \times 10^{-20} \Gamma_k T Z_k^2 e^{-(u_o^k - u_g^k) \xi_k(h\nu)}}{(h\nu)^3} ; h\nu \leq h\nu_g^k \quad (2.8a)$$

$$\sigma_k^C(h\nu) = \frac{6.26 \times 10^{-20} \Gamma_k T Z_k^2 e^{-(u_o^k - u_g^k) \xi_k(h\nu)}}{(h\nu)^3} + \sum_{\text{lower states, } i} \frac{N_i^k}{N^k} \sigma_i^{b-f}(h\nu) ; h\nu \geq h\nu_g^k \quad (2.8b)$$

The limiting frequency $h\nu_g^k$ corresponds to the lowest excited state above which the sum over states required by Eq. (1.1) can be replaced by an integration. Its selection must be based on the term structure of the particular atom under consideration, bearing in mind that it should be valid for all ℓ levels of Group A. For frequencies greater than $h\nu_g^k$, bound-free transitions from low-lying states having an ionization energy greater than $h\nu_g^k$ but less than or equal to $h\nu$ must be included specifically.

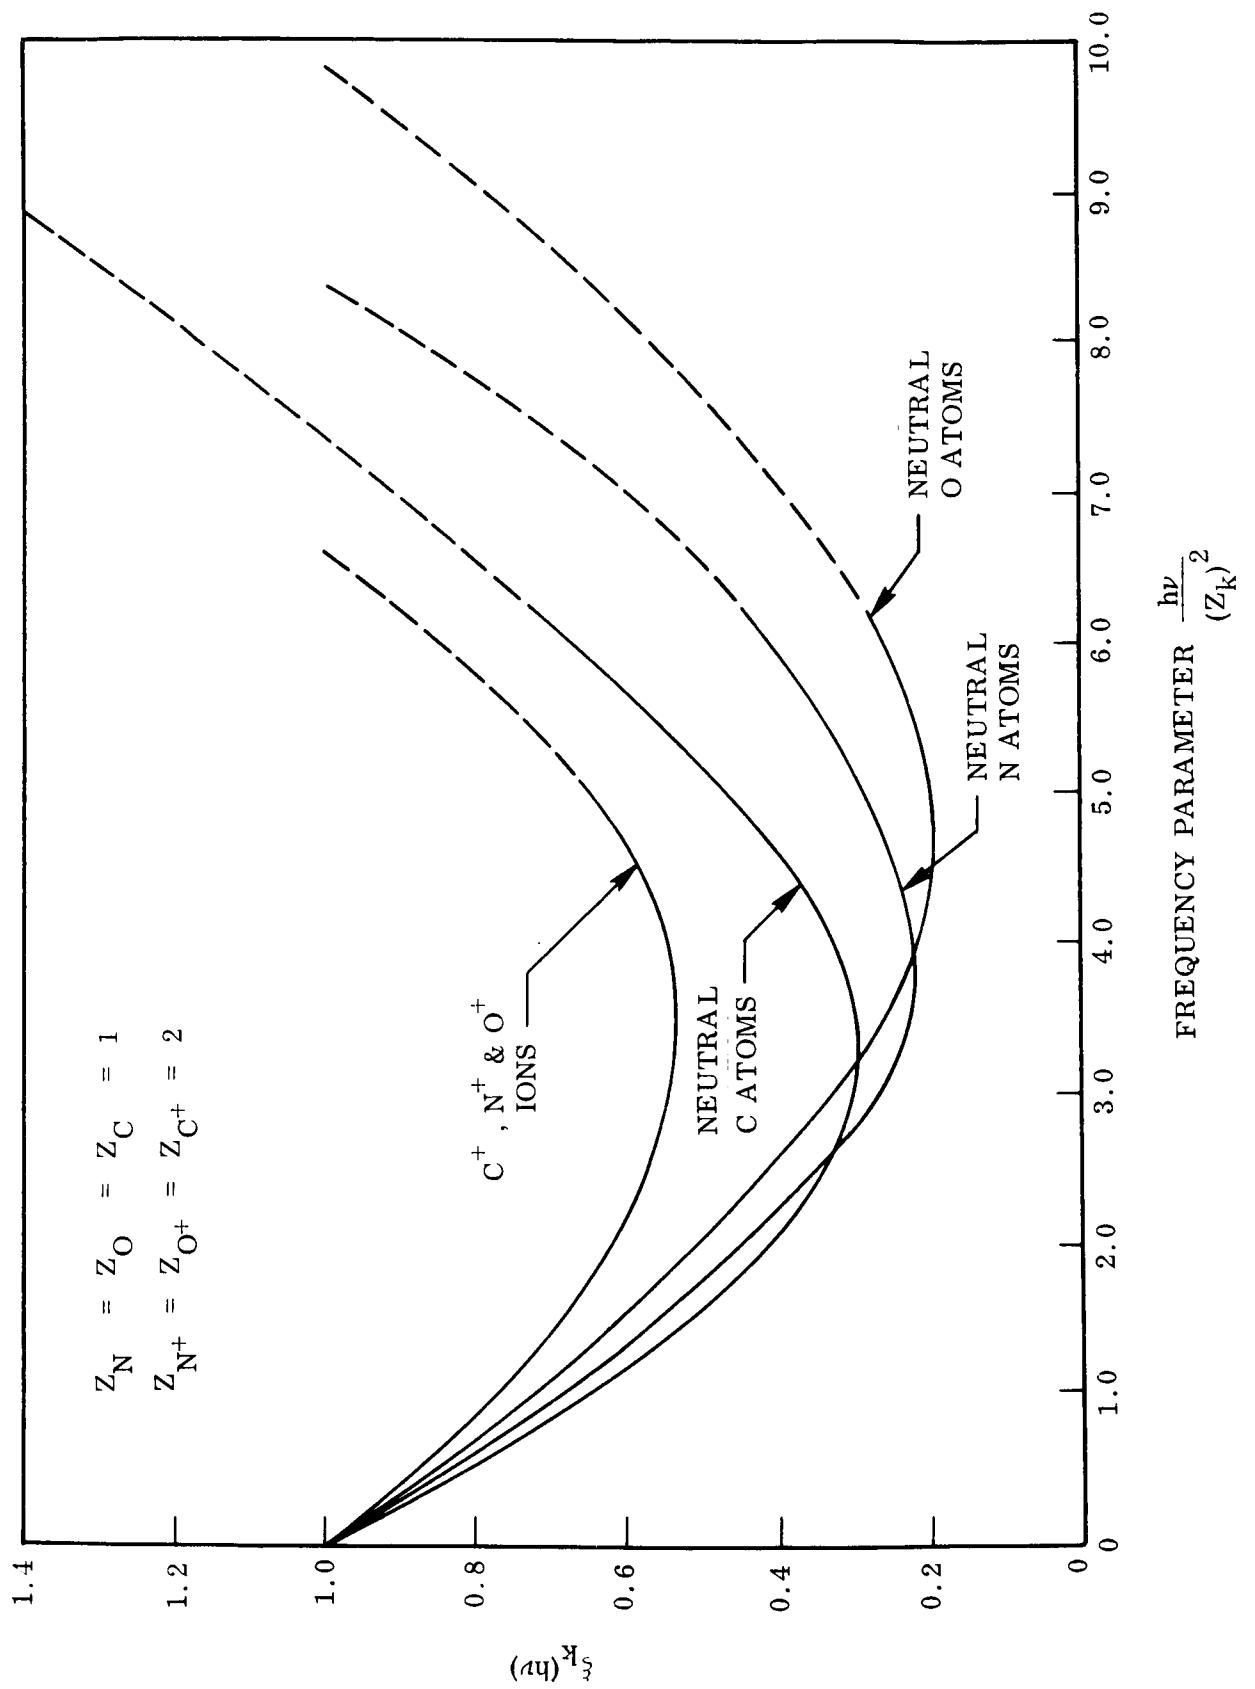

Fig. 2-1 Quantum-Mechanical Correction Factor $\xi_k(h\nu)$

The cross sections for the relatively small number of individually included states [see Eq. (2.8a)] can be taken from detailed calculations without any significant complication of the approximate method. Moreover, by using relatively exact cross sections for the lower states, the absorption coefficient thus obtained is accurate in the important spectral region where the large photoionization edges occur.

The validity of Biberman's method has been checked by comparing cross sections for neutral nitrogen atoms as calculated from Eqs. (2.8a) and (2.8b) with the detailed data of Armstrong et al. This comparison is shown in Figs. 2-2, 2-3, and 2-4 for temperatures of 10,000°, 15,000°, and 20,000°K. It should be noted that the cross sections for the low-lying states considered individually in Eq. (2.8b) have been taken directly from Armstrong's results. Hence, agreement at high frequencies ($h\nu > h\nu_g$) is effectively guaranteed. However, at low frequencies, where many important states contribute to the summation in Eq. (1.1), the approximate theory provides accurate closed-form expressions for the continuum cross section.

2.1.2 Photoionization Edge Shifts

The continuum cross-section data tabulated in Section 4 have not been corrected for plasma interactions. It is possible to account for such corrections in an approximate manner, thus avoiding tabulation of cross sections (for all temperatures) over a range of density values. The principal result of plasma interactions as far as continuum cross sections are concerned is a shift in the photoionization edges to lower frequencies. Armstrong (Ref. 14) has shown that, in the temperature and density range of interest, the shift is a result of merging of the higher bound state energy levels.* He shows that the frequency shift (in eV) is given by

$$\Delta(h\nu) = \frac{4.71 \times 10^{-6} N_e^{2/7}}{(kT)^{1/7}}$$

*A further discussion of the advance of the series limit is given in Ref. 1.

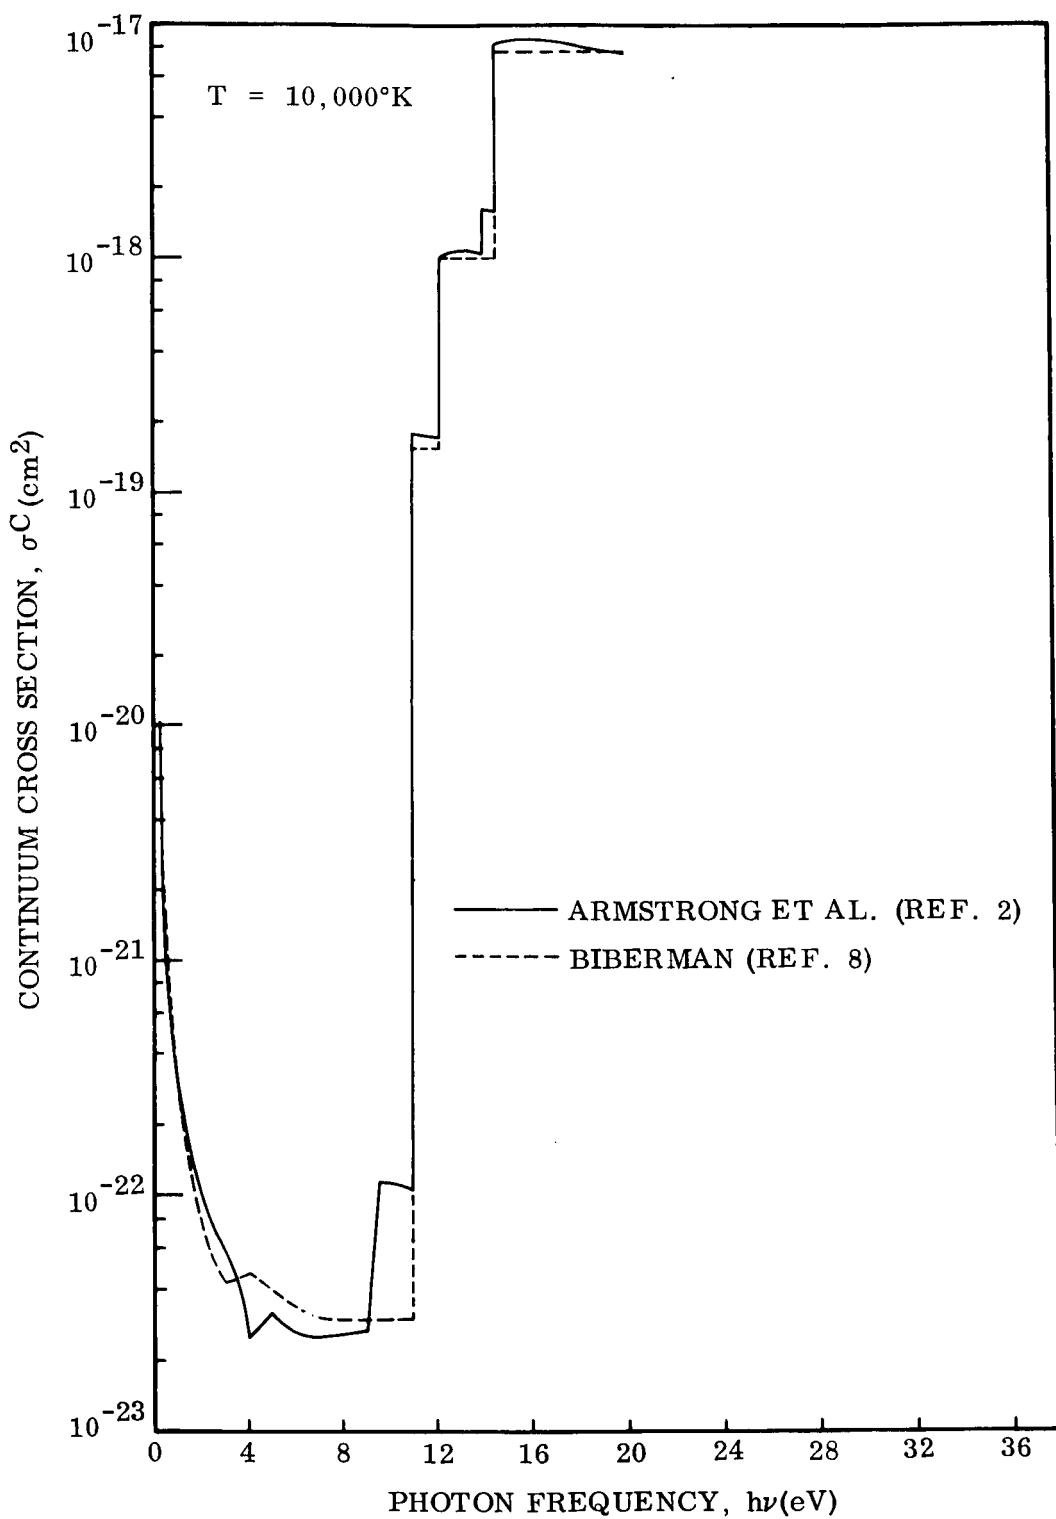

Fig. 2-2 Total Effective Continuum Cross Sections for Neutral Nitrogen Atoms, NI.
 $T = 10,000^\circ\text{K}$

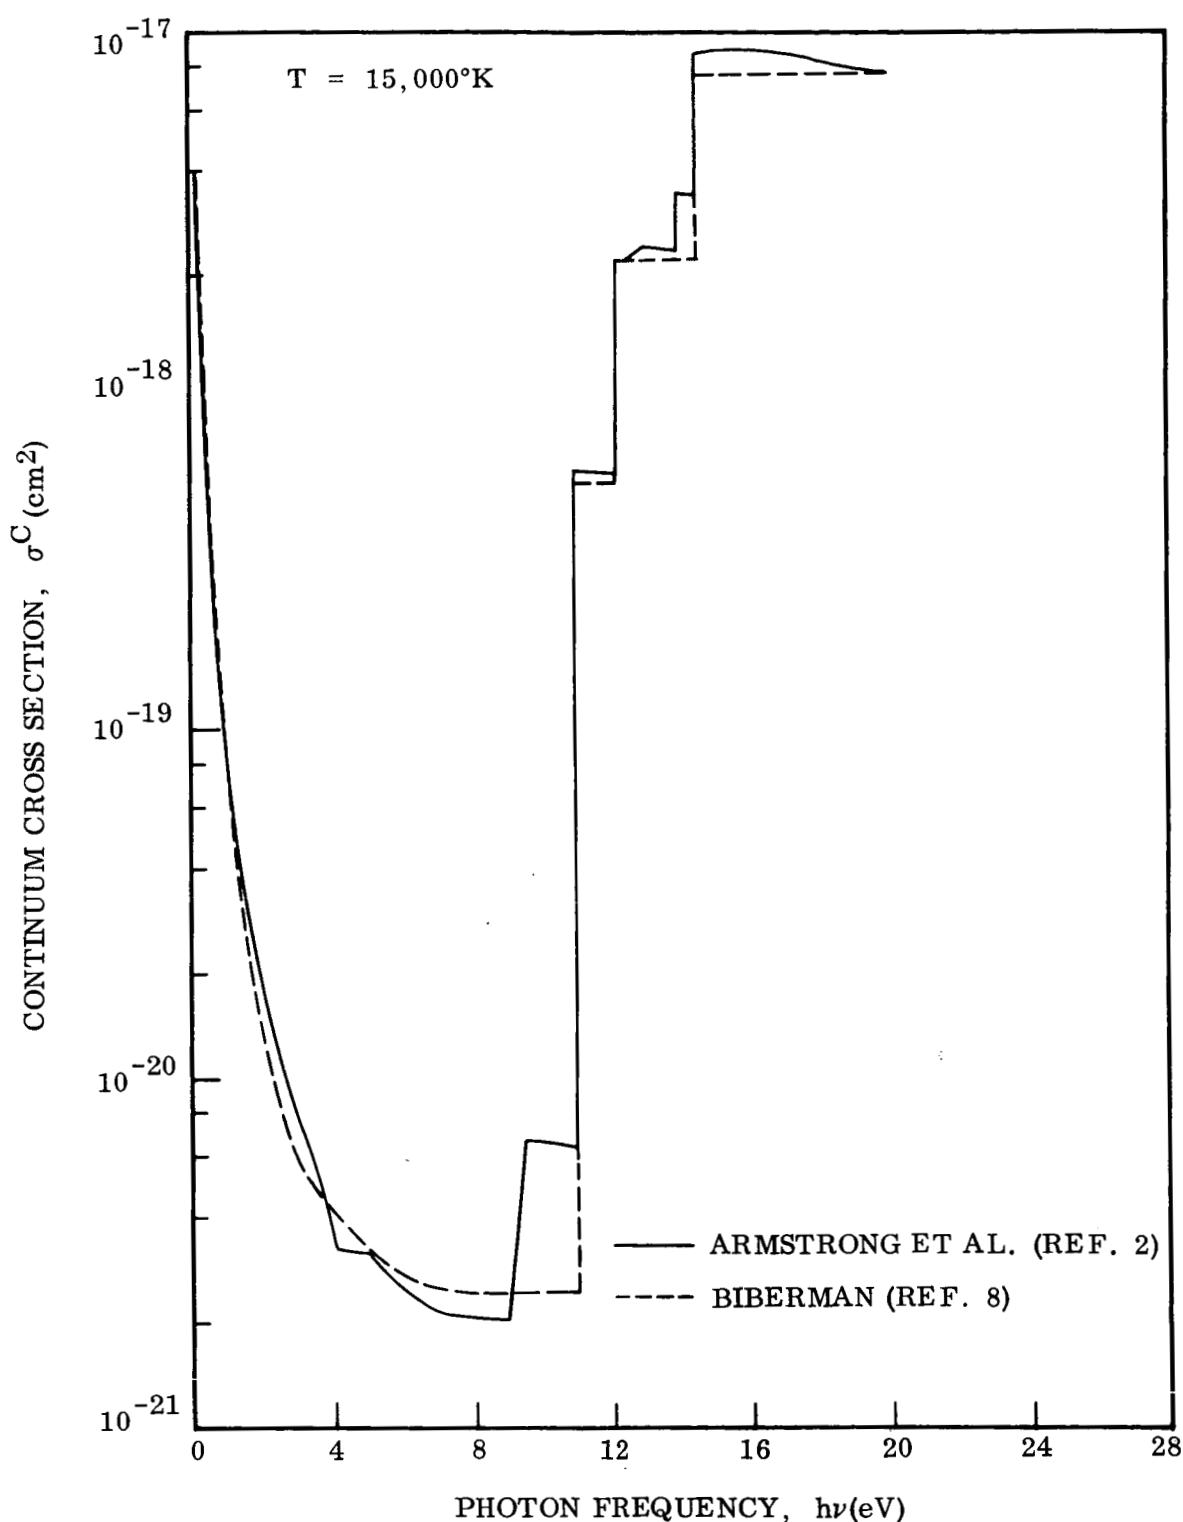

Fig. 2-3 Total Effective Continuum Cross Sections for Neutral Nitrogen Atoms, NI.
 $T = 15,000^\circ\text{K}$

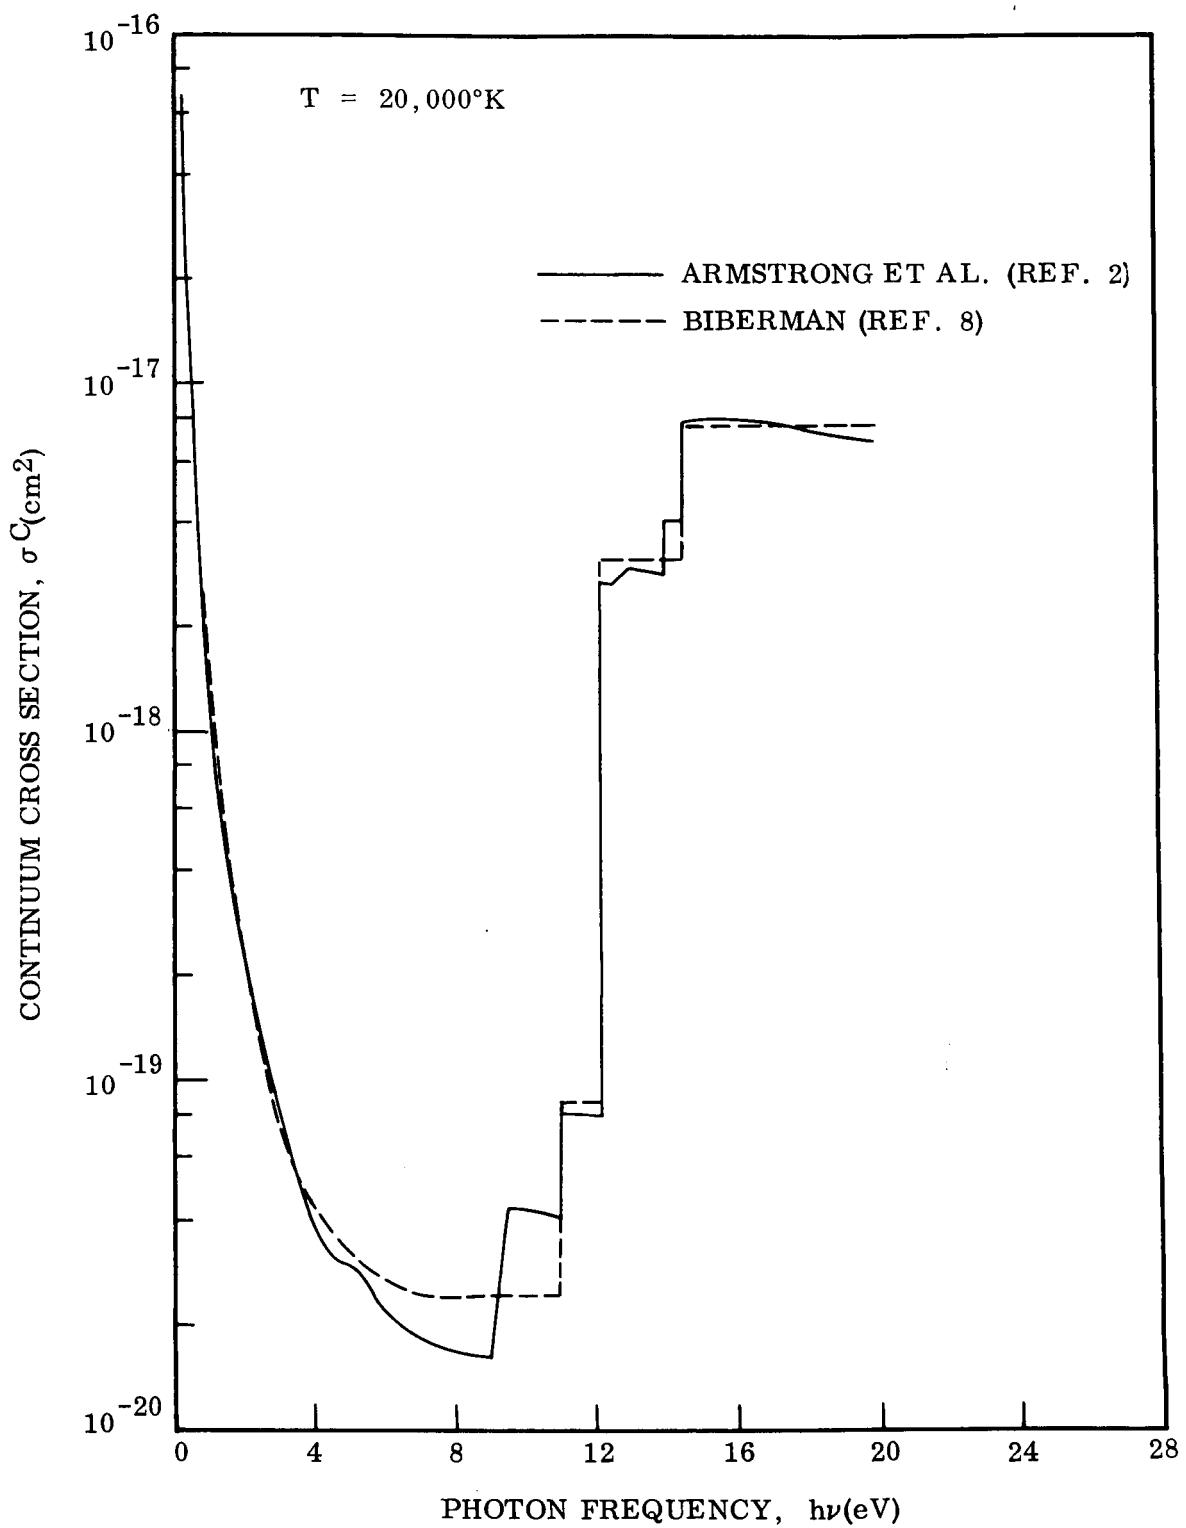

Fig. 2-4 Total Effective Continuum Cross Sections for Neutral Nitrogen Atoms, NI.
 $T = 20,000^{\circ}\text{K}$

The effect of the shift at the lower frequencies where the photoionization edges are smeared out is to increase the effective continuum cross section by a factor of $\exp[\Delta(h\nu)/kT]$. Thus, in Biberman's approximate theory, Eq. (9a) of Ref. 8, this exponential factor is introduced. At the higher frequencies, the contribution from the high-lying states is unaffected [the first term in Eq. (9b)]; however, the photoionization from edges of the individually calculated low-lying states [the second term in Eq. (9b)] must be shifted to lower frequencies by the amount $\Delta(h\nu)$. This edge shift at higher frequencies is significant in radiation transport calculations.

2.2 TABULATED DATA ON TOTAL EFFECTIVE CONTINUUM CROSS SECTIONS

Tables 4-1 through 4-6 present the total effective continuum cross section for neutral and singly ionized atoms of carbon, nitrogen, and oxygen at various temperatures. Each table lists the following data: the spectral frequency (i. e., photon energy) in electron volts; the spectral wavelength in Angstrom units; under a specified temperature value in °K, a list of the total effective continuum cross section in square centimeters. For each species, cross-section data are presented for temperatures between 3000°K and 24,000°K in 1000°K intervals.

Section 3

LINE ABSORPTION CROSS SECTIONS

3.1 THEORETICAL METHODS

The line contribution to the absorption coefficient arises when a photon is absorbed as the result of a bound-bound electron transition of the atomic system. Unlike the continuous contribution where an absorption cross section at a given photon energy is determined, the discrete contribution is determined in terms of the total probability for absorption integrated over all photon energies (Refs. 4 and 15),

$$\int_0^{\infty} \sigma_{nn'}^{b-b}(h\nu) d(h\nu) = \frac{\pi e^2}{mc} f_{nn'} \left(1 - e^{-h\nu_{nn'}/kT} \right) \quad (3.1)$$

where $f_{nn'}$ is a dimensionless (absorption) oscillator strength (i.e., the so-called f-number).

Armstrong et al. (Ref. 2) have calculated multiplet, supermultiplet, and transition array f-numbers for transitions in neutral and multiple ionized nitrogen and oxygen atoms. The number of transitions included is complete in the sense that all allowed transitions under L-S coupling are considered. The theoretical methods underlying these calculations are described in Ref. 2. The resulting compilation of f-number data contains much more data than is required for transport calculations. For example, in excess of 2,000 total transitions are listed for nitrogen species. To avoid presenting an excessive amount of data, most of which would not be useful in transport calculations, the transitions have been screened to include only those which are significant based on the rules listed below. First, only neutral and singly ionized atoms are considered since, for temperatures less than 2 eV and at densities where local thermodynamic

equilibrium is likely to be valid, the number densities of doubly or higher ionized atoms is very small. Second, those transitions for which the lower state principal quantum n is greater than or equal to 4 are not listed. These transitions ($n \geq 4$) can be adequately handled by the integral treatment proposed by Biberman and his colleagues (Refs. 16 and 17). Finally, our experience resulting from a detailed investigation of line transport in a nitrogen plasma has shown that for a given transition to be significant, the product of the number density of the lower state,* the f-number, and line width must be comparable to a similar product of neighboring lines.

The existing f-number calculations of Armstrong et al. (Ref. 2) did not include carbon atoms. The available data on transitions in OIII and OIV were used to determine the allowed transitions in CI and CII and corresponding relative multiplet strengths. The dipole integrals required to complete the carbon f-number calculation [see Eq. (4.3) in Ref. 2] were obtained using an existing computer code to calculate Hartree-Fock wave functions.** Calculations were performed for those transitions which our experience with nitrogen indicated would be significant in transport problems.

The selected transitions for carbon, nitrogen, and oxygen atoms are tabulated in Section 4. Included in the f-number tabulations are data from the recent NBS compilation of transition probabilities (Ref. 18). The NBS values are a result of a critical data review program and represent the most reliable data from both experimental and theoretical sources. The NBS f-numbers which are taken from experimental sources are clearly to be preferred over our data. A considerable number of important transitions are not included in the NBS compilation, but the data that are available provide a means of evaluating the accuracy of our theoretical calculations.

*A convenient tabulation of relative population numbers of the atomic states of nitrogen and oxygen atoms is available in Ref. 11.

**The authors are indebted to Dr. Paul Kelly, Lockheed Palo Alto Research Laboratory, for his generous assistance in making available the computation codes required to calculate dipole integrals for the carbon transitions.

For emission-dominated transport problems, a knowledge of $f_{nn'}$ for all significant transitions is adequate. For the more general case when absorption is important, it is necessary to know the details of the frequency-dependent absorption cross section for each transition, i.e., the line absorption shape. It is convenient to represent the bound-bound cross section $\sigma_{nn'}$, as (Ref. 2)

$$\sigma_{nn'}(\nu) = \frac{\pi e^2}{mc^2} f_{nn'} b_{nn'}(\nu) \left(1 - e^{-h\nu_{nn'}/kT} \right) \quad (3.2)$$

where $b_{nn'}(\nu)$ represents the shape of the line, normalized according to

$$\int_0^\infty b_{nn'}(\nu) d\nu = 1 \quad (3.3)$$

For many plasma conditions of interest, the dominant line broadening mechanism is Stark broadening under the electron impact approximation (Refs. 1 and 2). For impact broadening the lines acquire a Lorentz shape (Ref. 2),

$$b_{nn'}(\nu) = \frac{\gamma_{nn'}/\pi}{[\nu - (\nu_{0,nn'} - d_{nn'})]^2 + \gamma_{nn'}^2} \quad (3.4)$$

where $\nu_{0,nn'}$ is the frequency corresponding to the unperturbed transition from state n to n' , $d_{nn'}$ is the shift in the line center, and $\gamma_{nn'}$ is the (half) half-width of the line.

In the line broadening theory outlined in Ref. 2, the following expression is derived for the electron impact half-width.*

$$\gamma_{nn'} = \frac{4\pi N_e}{3} \int_0^\infty \left(\frac{n}{mv} \right)^2 f(v) \sum_m \left\{ \frac{\text{Max}(\ell_{n'}, \ell_m)}{(2\ell_{n'} + 1)} \left[\int_0^\infty P_{n'} r P_m dr \right]^2 \frac{\pi}{\sqrt{3}} g(n', m) \right\} dv \quad (3.5)$$

*Note that in Ref. 2 it is pointed out that only the broadening of the upper state n' is considered in the half-width determination. Hence, all transitions to a given upper state will have the same half-width.

where the sum is over all states accessible to electrons with energy $mv^2/2$. In Ref. 2, two basic approximations were made to simplify Eq. (3.5). First, it is assumed that, for essentially all electrons in the Maxwellian distribution $f(v)$, all allowed transitions to states m are accessible. This approximation overestimates the width. The second approximation sets the Gaunt factor $g(n', m)$ to unity, which underestimates the width. Hence, these two approximations taken together tend to compensate the error in each. With these approximations the summation in Eq. (3.5) can be removed from the integral and replaced by the sum rule,

$$\sum_m \left\{ \frac{\text{Max}(\ell_{n'}, \ell_m)}{2(\ell_{n'} + 1)} \left[\int_0^\infty P_{n'} r P_m dr \right]^2 \right\} = \frac{1}{2} \left(\frac{\mu_{n'}}{Z_{\text{res}}} \right)^2 \left[5\mu_{n'}^2 + 1 - 3\ell_{n'}(\ell_{n'} + 1) \right] \quad (3.6)$$

Then the following closed-form solution for the temperature-dependent half-width is obtained,

$$\gamma_{nn'} = \frac{6.37 \times 10^{-23} N_e}{\sqrt{kT(eV)}} \left(\frac{\mu_{n'}}{Z_{\text{res}}} \right)^2 \left[5\mu_{n'}^2 + 1 - 3\ell_{n'}(\ell_{n'} + 1) \right] \quad (3.7)$$

Half-widths calculated from Eq. (3.7) when compared with Griem's more detailed solutions (Ref. 1) showed that the above approximations are not applicable in the temperature range of interest. As a result, half-widths were calculated using the general theory of electron impact broadening as set forth in Ref. 1.* The dipole integrals required for a detailed half-width determination were available from the f-number calculations. In most cases, it was found that only the nearest (in energy separation) four or five states had to be included in the summation over available states [see Eq. (3.5)]. It should be emphasized that underlying the electron-impact theory is the requirement that the energy states be isolated. That is, the

*The investigation and subsequent reevaluation of electron impact half-widths was performed by Dr. R. Johnston, Lockheed Palo Alto Research Laboratory.

energy separation between adjacent states must be larger than the broadened width of a given state. Since the broadening increases with increasing electron density, at sufficiently high electron densities overlapping of states will occur, with the result that the calculated line widths are invalid and transitions to these states result in non-Lorentzian line shapes. A comparison of the calculated half-widths with the limited data of Ref. 1 shows agreement to within about 20 percent and a similar temperature dependence.

Electron impact broadening theory (Ref. 1) predicts a shift $d_{nn'}$ in the line center. The line shifts were determined simultaneously with the half-width calculations. The sign convention employed to designate the direction of the line shift is the following: if $d_{nn'}$ is positive, then the line center is shifted to lower frequencies [see Eq. (3.4)].

Results of a series of calculations over a wide temperature range showed that the half-widths and line-shifts (normalized with respect to electron number density) are weakly dependent on temperature. Therefore, over the temperature range of interest it was necessary only to provide calculations at relatively widely spaced intervals. These are chosen as $T = 2,500^\circ, 5,000^\circ, 10,000^\circ, 15,000^\circ, 20,000^\circ$, and $25,000^\circ\text{K}$. The half-width and line-shift data tabulated in Section 4 have been divided by the number density of electrons N_e [see Eq. (3.5)] in order to remove the density dependence.

3.2 TABULATED DATA ON ATOMIC LINE TRANSITIONS

Tables 4-7 through 4-12 present a tabulation of the f-numbers for bound-bound transitions in neutral and singly ionized atoms of carbon, nitrogen, and oxygen. Each table lists the following data: a number designating the transition; a code number identifying the lower state; a code number identifying the upper state; the energy difference (in electron volts) between the two states; the corresponding photon wavelength (in Angstrom units); a theoretically determined f-number using LMSC data; and an f-number taken from the NBS compilation. The transitions are listed in order of increasing energy difference.

Each transition is identified by the atomic configuration for the lower and upper states. The atomic configuration is specified by an eight-digit code number (Ref. 2) (ij , kk' , $n\ell$, SL). The ij digits designate the atom and charge state, as follows:

- $i = 0$ oxygen
- $i = 1$ nitrogen
- $i = 2$ carbon
- $j = 1$ neutral
- $j = 2$ singly ionized

The next two digits, kk' , designate the core configuration according to the list provided in Table 3-1 (reproduced from Ref. 2). The n digit is the principal quantum number of the outermost populated shell. The ℓ digit is the orbital quantum number of the outermost populated shell. The S digit is the spin multiplicity, and the L digit is the total orbital angular momentum for Russell-Saunders L-S coupling. When $n' \geq 4$, transitions are summed over all L-S terms and designated $S = 0$, $L = 0$. Hence, for $n' \geq 4$ the transition listed is no longer a single multiplet but rather a sum of multiplets.

As an example of the above identification code, the resonance transition in NI has the following interpretation:

<u>Lower Term</u> <u>(Ref. 3)</u>	<u>Code</u>	<u>Upper Term</u> <u>(Ref. 3)</u>	<u>Code</u>
$2p^3 4S^0$	1101 2140	$2p^2 (^3 p) 3s^1 P$	1101 3041

Tables 4-13 through 4-18 present a tabulation of the electron impact half-widths and line shifts for bound-bound transitions in neutral and singly ionized atoms of carbon, nitrogen, and oxygen. Each table lists the following data: a number designating the transition; a code number identifying the lower state; a code number identifying the upper state; the energy difference (in electron volts) between the two states; the corresponding photon wavelength (in Angstrom units); a series of pairs of half-widths and line-shifts (both in electron volts) at specified temperatures.

TABULATED DATA

In the following sets of tables, the detailed spectral absorption coefficients for neutral and singly ionized carbon, nitrogen, and oxygen atoms are presented. Tables 4-1 through 4-6 give the total effective continuum cross sections for the various atomic species according to the format described in subsection 2.2. Tables 4-7 through 4-12 give the line transitions and f-numbers for the various atomic species according to the format described in subsection 3.2. Tables 4-13 through 4-18 give the line transitions and electron impact half-widths and line center shifts according to the format described in subsection 3.2. The numerical data are presented in floating point notation with an exponent of the base 10 by which the number is multiplied.
